# Parallel Systems

DQC

## Parallelism/Concurrency: Why?

- Simpler (more natural, straightforward) modeling of real world processes.
- Robust, Fault Tolerant Systems.
  - If a process crashes the crash is contained.
- Computation time optimization/speedup.
  - Real-time compliance results (partial results) delivered on time.

・ロト ・同ト ・ヨト ・ヨ

#### Program Performance Metrics: Speedup

- The parallel run time (Tpar) is the time from the moment when computation starts to the moment when the last processor finished its execution
- The speedup (S) is defined as the ratio of the time needed to solve the problem on a single processor (Tseq) to the time required to solve the same problem on parallel system with "p" processors (Tpar):

- relative Tseq is the execution time of parallel algorithm executing on one of the processors of parallel computer
- real Tseq is the execution time for the best-know algorithm using one of the processors of parallel computer
- absolute Tseq is the execution time for the best-know algorithm using the best-know computer

# Program Performance Metrics: Efficiency

• The efficiency (E) of parallel program is defined as a ratio of speedup to the number of processors

- The cost is usually defined as a product of a parallel run time and the number of processors
  - С
- The scalability of parallel system is a measure of its capacity to increase speedup in proportion to the number of processors

#### Stone's Table

Speedup (S)	Type of Algorithms
$\alpha * p$	matrix computations, discretization
$\frac{\alpha * p}{\log_2 p}$	sorts, linear recursions, evaluation of polynomials
$\alpha * \log_2 p$	search for an element in a set
$\alpha$	certain non-linear recursions

Where p is a number of used processors and  $\alpha$  is a positive number smaller then 1 which depends on the machine/architecture.

# Scalability of Parallel Systems

- The parallel system is scalable if it maintains speedup at a fixed value while increasing the number of processors and the size of the problem.
- The scalability of a parallel system is a measure of its capacity to increase speedup in proportion to the number of processors.
- The scalability reflects a parallel system ability to utilize increasing processing resources effectively.

#### Mesh Architecture

Adding *n* numbers on the mesh with *p* processors:  $\sqrt{p}$  steps.

DQC

(日) (四) (三) (三)

#### Mesh: details

- In the first step each processor locally adds its n/p numbers, in the next steps half partial sums are transmitted to adjacent processors and added, the procedure finished when one chosen processor gets the final sum
- Assume that it takes one unit of time both to add two numbers and to send a number between two directly connected processors
- Then adding the n/p numbers local to each processor takes n/p 1 time
- The p partial sums are added in  $\sqrt{p}$  steps (one addition and one communication:  $2 * \sqrt{p}$ )

## Mesh: Speedup, Efficiency

• Thus the total parallel run time can be approximated by:

$$T_{par} = n/p + 2 * \sqrt{p}$$

• Since serial run time can be approximated by n the expression for speedup and efficiency are as follows:

$$S = \frac{n * p}{n + 2p\sqrt{p}}$$
$$E = \frac{n}{n + 2p\sqrt{p}}$$

#### Speedup versus the number of processors

DQC

# Speedup: Conclusions

- For the given problem instance, the speedup does not increase linearly as the number of processors increases
- A larger instance of the same problems yields higher speedup and efficiency for the same number of processors

# Scalability, recap.

- The parallel system is scalable if it maintains speedup at a fixed value while increasing the number of processors and the size of the problem.
- The scalability of a parallel system is a measure of its capacity to increase speedup in proportion to the number of processors.
- The scalability reflects a parallel system ability to utilize increasing processing resources effectively.

#### Amdahl's Law

- When executing a parallel program we can distinguish two program parts: sequential part (Pseq) which needs to be executed sequentially using one processor parallel part (1-Pseq) which can be executed independently using number of processors
- Let's assume that if we execute this program at single processor the serial execution time will be t1. Then if p indicates the number of used processors during parallel execution the parallel run time can be expressed by:

$$T_{par} = t_1 * P_{seq} + (1 - P_{seq}) * t_1/p$$

• Speedup:

$$S = rac{t_1}{t_1 * P_{seq} + (1 - P_{seq}) * t_1 / p} \leq rac{1}{P_{seq}}$$

<ロト <回ト < 回ト < 回ト

## Amdahl's Law: Example

- Question : Suppose you want to achieve a speedup of 80 with 100 processors. What fraction of the original computation can be sequential?
- Answer: From Amdhal's law: speedup is limited by the sequential fraction of the program:

$$S = \frac{t_1}{t_1 * P_{seq} + (1 - P_{seq}) * t_1/p}$$
$$P_{seq} = \frac{\frac{p}{5} - 1}{p - 1}$$

• Thus:

• Then:

 $P_{seq}=0.0025$

#### Bottom Line

- Use parallelism if:
  - time limits,
  - a need for fastest computations.
- Additional requirements:
  - sequential part of the program,
  - parallel part of the program.
- Gain can be achieved on the parallel part only.
- Keep in mind communication lags.
